DOES JOB LOSS CAUSE ILL HEALTH?

MARTIN SALM*

Department of Econometrics and OR, Tilburg University, Tilburg, Netherlands

SUMMARY

This study estimates the effect of job loss on health for near elderly employees based on longitudinal data from the Health and Retirement Study. Previous studies find a strong negative correlation between unemployment and health. To control for possible reverse causality, this study focuses on people who were laid off for an exogenous reason – the closure of their previous employers' business. I find no causal effect of exogenous job loss on various measures of physical and mental health. This suggests that the inferior health of the unemployed compared to the employed could be explained by reverse causality. Copyright © 2009 John Wiley & Sons, Ltd.

KEY WORDS: job displacement; health; unemployment

1. INTRODUCTION

Unemployment is a major cause of economic insecurity for working-age Americans. Loss of employment is often linked with a loss of income and employer-provided health insurance, as well as the loss of valued relationships, status, and identity. Chan and Stevens (2002) find that job loss reduces earnings for near elderly employees 1 year after job loss by between 20 and 33%, and lower income might be a cause of deteriorating health (Adams *et al.*, 2003). There exists a well-documented negative relationship between unemployment and health (see discussion in Catalano *et al.*, 2000). However, such an association does not necessarily imply a causal relationship from unemployment to ill health. There is also empirical evidence that people in ill health are more likely to become unemployed (Arrow, 1996), and that unemployment spells are longer for people with health problems (Stewart, 2001). In order to study the causal relationship from unemployment to health it is necessary to control for the cause of entry into unemployment, and also to account for the fact that unemployment spells might be longer for people in ill health.

This study uses data from the Health and Retirement Study (HRS), a nationally representative survey of near elderly Americans. Several features make this data set especially well suited for examining the causal effect of job loss on health: (1) The HRS includes detailed information on the causes of termination of employment contracts. In this paper, I only consider individuals who lost their job because of business closure, which is arguably exogenous to employees' health. (2) The HRS is a panel data set. (3) The HRS includes detailed information on demographics, health, income, education, health behaviors, job characteristics, and the ex-ante subjective probability of involuntary job loss. This information allows controlling for differences in characteristics between respondents who are affected by job loss and respondents who are not affected by job loss.

This study uses a differences-in-differences estimation approach. It follows a cohort of initially employed individuals and compares the subsequent changes in health for respondents who lose their jobs with a control group of respondents who do not lose their jobs. My definition of job loss includes people who have been laid off because of business closure at any point of time within a 2-year period, independent of their unemployment status at the time of the second interview. In this way, I control both for a possible relationship between ill health and entry into unemployment and for a possible relationship between ill health and the subsequent length of unemployment spells. This approach thus makes it possible to consistently estimate the causal effect of job loss on health.

This study contributes to a literature that examines the effects of job loss and unemployment on health (e.g. Bjorklund, 1985; Mayer *et al.*, 1991; Gerdtham and Johannesson, 2003; Browning *et al.*, 2006; Bockerman and Ilmakunnas, 2009; Sullivan and von Wachter, 2009; Eliason and Storrie, 2009). Numerous studies compare various measures of physical and mental health between employees and unemployed individuals, often with a focus on how the relationship between unemployment and health differs between specific racial and ethnic groups (Rodriguez *et al.*, 1999; Catalano *et al.*, 2000), gender, family role, and social class (Artazcoz *et al.*, 2004; Price *et al.*, 2002; Dew *et al.*, 1992), unemployment benefit type (Rodriguez, 2001), and community characteristics (Turner, 1995). These studies mostly find that the unemployed are in worse physical and mental health than employees. However, entry into unemployment could also be caused by ill health. A number of recent studies control for this possible source of reverse causality by examining the effects of mass-layoffs on health based on administrative data. Sullivan and von Wachter (2009) find a large effect of mass layoffs in Pennsylvania in the 1970s and 1980s on higher mortality for a sample of male workers with stable employment relationships whose firms employed at least 50 employees. Eliason and Storrie (2009) find that job displacement due to establishment closure also increased mortality in Sweden. In contrast, Browning *et al.* (2006) find no significant effect of job displacement on hospitalization for diseases of the cardiovascular and digestive system for workers who have been displaced by mass-layoffs in Denmark.

My study adds to the previous literature on the effect of layoffs on health by considering a broad range of physical and mental health outcomes that have not been examined before, such as self-reported change of health, limitations in activities of daily living (ADL), subjective longevity expectations, depression, and physician-diagnosed mental health conditions. This study also looks at a different sample that includes workers who have not been in stable employment relationships and workers who were employed by small firms. One advantage of this study compared to previous studies is that I control for a more detailed list of individual characteristics, which includes the ex-ante subjective probability of job loss, which are not available in administrative data. Without controlling for detailed individual characteristics, differences in the subsequent health of workers affected by layoffs and workers who are not laid off might reflect not the effect of layoffs on health, but could also be explained by different individual characteristics.

In this study, I find no significant effect of exogenous job loss on health for any of my specifications. This finding is robust for various measures of physical and mental health, and this result is confirmed across various subgroups of the population, which are defined by gender, race, marital status, income, and education level, as well as previous working conditions. There is no negative effect of job loss on health, neither for employees who did anticipate being displaced, nor for employees who did not anticipate being displaced, and I also find no effect of spousal job loss on health. In contrast, causes of unemployment that are arguably endogenous to health, such as leaving a job for health reasons, are both common in the sample, and are associated with a substantial deterioration in health. While a lack of statistically significant results does not prove that job loss has no effect on ill health, my results suggest that the negative correlation between health and unemployment could be explained by reverse causality.

The paper proceeds as follows: Section 2 outlines the identification strategy. Section 3 describes the data. Section 4 presents and discusses the estimation results. Section 5 concludes the paper.

2. IDENTIFICATION STRATEGY

The main parameter of interest in this study is the average effect of job loss on the health of those who lost their job. A formal definition of this effect, similar to Heckman *et al.* (1997) is:

$$\alpha = E(Y(i, 1) - Y(i, 0)|D(i, 1) = 1) - E(Y(i, 1) - Y(i, 0)|D(i, 1) = 0) \quad (1)$$

where $Y(i, t)$ is the health of individual i at time t . The population is observed in a pre-treatment period $t = 0$, and a post-treatment period $t = 1$. I denote $D(i, 1) = 1$ if individual i has been affected by job loss between periods $t = 0$ and $t = 1$, and $D(i, 1) = 0$ otherwise.

The parameter α represents the difference between the health change of people affected by job loss and their hypothetical (counterfactual) health change if they had not been affected by job loss. Unfortunately, the counterfactual is never observed. Therefore, I need to assume that without job loss the health of people who in fact have been laid off would have evolved in the same way as it did for people with the same observed characteristics who have not been laid off. If i' is an individual in the control group (not laid off) with the same observed characteristics as i , an individual in the treatment group (laid off), then this assumption can be stated as

$$E(Y(i, 1) - Y(i, 0)|X(i), D(i, 1) = 0) = E(Y(i', 1) - Y(i', 0)|X(i'), D(i', 1) = 0)$$

where $X(i)$ is a vector of observed characteristics predetermined at $t = 0$. It is necessary to control for a sufficiently detailed set of relevant characteristics $X(i)$, because on average people affected by job loss do not have the same characteristics as people who are not laid off. Not controlling for differences between these groups would lead to biased estimation results. If for example the average laid-off employee is poorer or less educated than the average employee who is not laid off, one might expect their health to evolve unfavorably compared to the health of the control group even in the absence of job loss. Observed characteristics in this study include information on demographics (age, gender, race), social status (marital status, education, income, wealth), health behaviors (smoking, obesity, and health insurance), and job characteristics (part-time employment, firm size, and industry). I also control for the ex-ante subjective probability of involuntary layoff. Stephens (2004) finds that the subjective probability of involuntary layoff includes information about the likelihood of subsequent job loss even after controlling for other characteristics, and that it is a good predictor of subsequent actual job loss. Including the subjective probability of involuntary layoff controls for unobserved heterogeneity between people affected by job loss and others, which other observed characteristics could not detect. The average treatment effect can be estimated by the following linear differences-in-differences regression equation:

$$Y(i, 1) - Y(i, 0) = \delta + X(i)'\pi + D(i, 1)\alpha + \varepsilon(i) \quad (2)$$

where the dependent variable is the change in health between period 0 (before the treatment) and period 1 (after the treatment), and $X(i)$ are assumed to be exogenous to the random error term $\varepsilon(i)$. The equation above can be estimated by standard regression methods such as least squares or ordered probit. I estimate the effects of job loss on several measures of health, and for alternative causes of job termination. These variables are described in the following section.

3. DATA AND DESCRIPTIVE STATISTICS

I use data from wave two to six of the HRS, which cover the time period from 1994 to 2002.¹ The HRS includes a sample of initially 7600 households (12 654 individuals), with at least one household member born between 1931 and 1941, and their spouses, who could be any age. The survey was administered

¹For a detailed description of the HRS, see Juster and Suzman (1995) and the HRS homepage (www.hrsonline.isr.umich.edu).

every 2 years. In 1998, a new sample was added to the survey, which consists of 'war babies' born between 1942 and 1947, and the data also include new spouses of previous wave respondents. The baseline estimation sample in this study consists of all persons who were working for pay at the time of the interviews for waves 2–5 and who were aged 63 or below at this time. This sample excludes persons who are self-employed. This leaves a sample of 20 396 observations. Of these, 4697 observations do not include information on subjective probability of involuntary job loss, 221 observations do not include information on industry sector, 92 observations have missing information on smoking, 59 observations do not include information on household income, and 9 observations have no information on household wealth.² The final sample for the baseline regression (Table III, column 4) consists of 15218 observations on 6867 individuals. The sample can include multiple observations over time for the same person.

For each observation, I use information from two waves, before and after treatment. Before treatment, all respondents work for pay. At the following interview 2 years later, some respondents do not work any more for their previous-wave employer. These individuals might be retired, unemployed, or work for a different employer. All respondents who did not work for their previous-wave employers were asked why they had left that employer. Possible answers included 'business closed', 'laid off/let go', 'poor health/disabled', and 'other reasons'. Respondents could give multiple reasons. My definition of exogenous job loss includes 369 observations (2.4% of the baseline sample) who answered that their previous employers' business closed. This definition excludes 17 observations who also stated that they quit by themselves or left for health reasons, and it includes 24 observations who also stated that they were laid off or let go. In total, 720 respondents stated that they were laid off/let go, 544 quit, and 507 left for health reasons. One concern with respect to the timing of job transitions is that respondents stopped working for their previous employers at different points of time during the 2-year period between interviews, and it could make a difference whether for example the previous employers' business closed just after the first interview or just before the second interview. This study estimates average effects.

Outcome variable is the change of health between waves, which is measured by various subjective and self-reported objective measures of health. One measure for change of health is the answer to a question how self-assessed health has changed since the last interview 2 years ago. Possible answers include 'much better', 'somewhat better', 'about the same', 'somewhat worse', and 'much worse'. The answer 'much better' is coded as 1 and 'much worse' is coded as 5. Another measure of health change is the change in limitations in ADL's since the previous interview. ADL include the ability to walk across a room, dress, eat, bath, use a toilet, and get in and out of bed without help. An additional measure of health change is the change in longevity expectations. Longevity expectations are measured as the subjective probability to live to age 75 or longer, and changes in answers between waves are measured relative to life-table averages. I also use two measures of change in mental health, the first of which is the change in CESD scores (Center for Epidemiologic Studies Depression Scale). Respondents are asked whether they agree or disagree with eight statements about their emotions during the past week such as whether they felt depressed much of the time. The CESD score is based on the answers to these questions and ranges from 0 (good mental health) to 8 (bad mental health). The second measure of mental health change is a binary variable that indicates whether there was a first incidence of a physician-diagnosed mental health condition between interview waves. Further, in one regression I use a measure of same-period self-reported overall health as dependent variable. Possible answers range from 'excellent' (codes as 1) to 'very good' (2), 'good' (3), 'fair' (4), and 'poor' (5).

One concern with respect to self-reported change of health is that the differences between categories might not be equal. For example the difference between 'much better' health and 'somewhat better'

²Mean values for self-reported health and for self-reported health change vary little after observations with missing answers are excluded. This suggests that item non-response is not systematically related to health or health change.

health might not be the same as the difference between ‘somewhat better’ health and ‘about the same health’. One solution to this potential problem is to use ordered probit estimation, which allows for different distances between categories.

Another question is whether self-reported health measures provide meaningful indicators of health status. Idler and Benyamini (1997) documented in a review of 27 studies that self-reported health measures are strongly correlated with mortality. Bath (2003) and Remle (2004, unpublished) also find that self-reported changes in health predict future mortality both for British data and the HRS. Another concern about self-reported health measures that has received a lot of attention in the literature is that self-reports of health might be biased depending on labor force status, if people out of work are more likely to report ill health in order to justify economic inactivity. Several previous studies found evidence for such a justification bias, while others found no evidence (see review by Currie and Madrian 1999, and discussion in McGarry 2004). This study uses several measures of health change. Some of those, such as subjective longevity expectations and physician-diagnosed mental health conditions, are not likely to be affected by justification bias. For other measures such as self-reported health change, it is possible that the estimates of the negative effect of job loss on health change are upward biased.

Explanatory variables include respondents’ age and binary variables for respondents who are female, black, married, have a high school degree, and for respondents who have a college degree. Additional explanatory variables are total household net wealth, and the logarithm of the total household income. Income and wealth are adjusted for consumer price inflation and represent real 1982–1984 prices. Also included are binary variables about health behaviors, whether the respondent is currently smoking, is obese, which is defined as a body mass index in excess of 30, or is covered by health insurance. Explanatory variables also include information on job characteristics such as a binary indicator for part-time work and five binary indicators for firm size, which is measured by the total number of employees at all locations (5–14 employees, 15–24 employees, 25–99 employees, 100–499 employees, and 500+employees, less than five employees is omitted category), as well as twelve binary indicators for industry sector (agricultural sector including forestry and fishery is omitted category). The subjective probability of job loss is based on the following question: ‘Sometimes people are permanently laid off from jobs that they want to keep. On the scale from 0 to 100 where 0 equals absolutely no chance and 100 equals absolutely certain, what are the chances that you will lose your job during the next year?’ One limitation of this study is that this question refers to the probability of involuntary job loss during a 1-year period after the interview, while this study examines layoffs during a 2-year period after the first interview.

Table I shows sample statistics for both the overall population and those affected by job loss. Table I is based on the sample included in the baseline regression (Table III, column 4). To some degree, people anticipate being laid off. For job losers, the average subjective probability of being laid off was 31% compared with 15.4% for the total population. However, a substantial fraction of laid-off persons did not previously expect to lose their employment. The fraction of laid-off respondents, who had previously stated that their probability of involuntary job loss was zero, amount to 37.1%, as compared to 54% for the full sample. Compared to the full sample people who are affected by job loss due to business closing are more likely to be female, married, and have a high-school degree, but much less likely to have a college degree. On average, people, who will lose their job, live in households with somewhat lower incomes, and substantially lower wealth, and they are more likely to work part time. They are more likely to smoke and be obese, and they are somewhat less likely to be covered by health insurance. Compared to the full sample, the sample of laid-off employees differs little in terms how stressful jobs are and how much physical effort they require. However, laid-off employees are more likely to receive low pay, which is defined as an hourly wage below \$4.72 in 1982–1984 prices. Laid-off employees also tend to work at smaller firms, and are more likely to work in manufacturing and retail sales and less likely to work in public administration and professional services.

Number of observations in baseline	15 218		369	

^aThe business closed sample excludes 14 respondents who also 'quit' their previous employment contract and 3 respondents who also 'left for health'.

^bOmitted category is firm size < 5 employees.

^cOmitted category is agricultural sector including forestry and fishery.

Laid-off respondents face a 10.8% probability to be unemployed at the time of the second interview, while this probability is only 1.6% for the entire sample. The probability that laid-off respondents will not be working at the time of the second interview is 39.2%, as compared to 19.5% for the full sample. Thus, many of the laid-off respondents in the sample leave the labor force. People who lose their job suffer a substantial drop in household income, on average –12.9% between waves, while average income stays constant in real terms for the entire sample. For respondents who do not work again after being laid off, the average drop in household income is –17.8%, while for people who work for pay in the interview after the job loss, the average reduction in household income is –9.7%. Thus, laid-off workers face on average a substantial drop in household income even if they find new employment.

4. RESULTS

4.1. Cross-section estimation of the relationship between unemployment and health

The regression results in Table II show the association between being unemployed and self-reported overall health. Unemployment status and self-reported overall health are both measured at the same time. The sample differs from the samples used in the following regressions by including not only respondents who work for pay at the time of the first interview, but also those who are unemployed. The regression presented in Table II replicates the cross-sectional approach taken in much of the previous literature on unemployment on health (for example Turner, 1995; Rodriguez, 2001; Artazcoz *et al.*, 2004). In line with previous studies, I find a significant negative association between unemployment status and self-reported health. However, this does not establish a causal link from unemployment to ill health, if people who are ill in the first place are also more likely to become and/or remain unemployed.

Table II. Cross-section regression of health on unemployment

	Health

Robust standard errors in brackets, clustered at respondent level.
 *significant at 10%; **significant at 5%; ***significant at 1%.
 Coefficients for binary wave variables not shown. Ordered probit estimation. Higher values for health represent worse health.

The coefficient of the effect of unemployment on health is 0.21.³ This implies that unemployment increases the probability of higher health categories, which represent worse health. The signs of the other dependent variables are as one might expect. Higher education, higher income, being female, and having health insurance coverage are associated with better health, while higher age, being black, working part time, smoking, and obesity correlate with worse health.

4.2. The average effect of job loss on health

Table III shows the estimated average effect of job loss on health for laid-off persons. Columns 1–4 show estimation results for different sets of covariates. None of the specifications shows a significant effect of job loss on health change. The negative estimation coefficient for the business-closed variable actually indicates that job loss is good for health. However, the coefficient is not statistically significant. The estimation coefficient of business closed becomes even more negative if additional covariates are added to the regression. The signs of the coefficients for the other covariates are mostly as expected. Higher education, income, and wealth are associated with improving health, while age, smoking, and obesity are associated with worsening health. Black race is associated with improving health. This result could reflect different standards of black respondents in answering questions about self-reported change of health. The subjective probability of job loss is associated with a significant subsequent deterioration

³The values of coefficients from ordered probit estimations do not have a straightforward intuitive interpretation, because the size of the marginal effect of unemployment on health varies with the values of the other explanatory variables.

Table III. The causal effect of job loss on health

Robust standard errors in brackets, clustered at respondent level. *significant at 10%; **significant at 5%; ***significant at 1%. Coefficients for binary wave variables not shown; Columns (3) and (4) also include binary variables for five firm size categories and twelve industry categories, which are not shown. All columns show ordered probit estimations. Higher values for health change represent worsening health.

in health. This can be explained either if the risk of being laid off itself is harmful to health, or if the subjective probability of job loss is correlated with other characteristics that cause ill health.

One concern with respect to interpreting the results in Table III is that respondents might use different scales for answering questions about self-reported change of health. Such scales could also vary systematically between subgroups of the population. One approach to account for different scales across subgroups (index sifting) is to include variables for demographic and socio-economic characteristics. The specifications in columns 3 and 4 of Table III include a detailed range of such characteristics.⁴

In summary, the results in Table III show no significant causal effect of job loss on ill health. One concern is that the sample size (369 individuals lose their job due to business closure) is insufficient to determine a significant effect. In order to test for the robustness of the result that job loss does not cause ill health I estimate additional specifications for various measures of physical and mental health. I also estimate the effect of job loss on health separately for subgroups based on demographics, job characteristics, and on previous expectations about the probability of involuntary job loss. Further,

⁴One approach to control for different distances between cut-off points across subgroups of the population (cut-off point shifting) is to use a generalized ordered probit model. In analysis not shown I estimate a generalized ordered probit for the baseline specification in column 4 of Table III, and I find that business closed is not significantly different from zero at any of the cut-off points.

I examine whether there is any effect of job loss on health for a longer time period, and I also estimate the effect of spousal job loss on the health of respondents.

In addition to testing for the robustness of the result that job loss does not cause ill health, I also examine whether the observed correlation between unemployment and health can be explained by reverse causality. Table IV compares how subsequent health changes vary by different reasons of job termination. Previous studies differ in what reasons for unemployment they include in their analysis. For example, Bjorklund (1985) and Rodriguez *et al.* (1999) include all reasons for unemployment, while Catalano *et al.* (2000) include only those who were involuntarily laid off. Layoffs could be related to health, if for example some people are laid off because of sickness-related work absences. A simple test on how the definition of job loss influences the estimated effects of job loss on health is to estimate the effect of job loss on health for various reasons of job termination and compare the results. As discussed above, I assume that business closure is exogenous to health change, while being laid off, quitting, and leaving for health reasons might be endogenous. I find that being laid off, which could be for any reason, has no significant effect on health change. People who quit their job subsequently experience improving health. This finding could be explained if these respondents quit for example because they started a better job with a new employer. However, people who leave their job for health reasons experience a very strong negative change in their health. As shown in Table I, leaving a job for health

Table IV. Endogenous causes of job termination

Higher values for health change represent worsening health.

reasons is also quite common in this age group. In summary, these results suggest that the subsequent change of health varies substantially for different reasons of job termination. This implies that reverse causality can bias estimation results if the reason for entering unemployment is not exogenous.

Table V presents the effect of job loss for several measures of health change. Measures of health change in Table V include the change in limitations of activities in daily living, the change in longevity expectations, the change in the CESD score for mental health, and first incidence of physician-diagnosed mental health conditions. For all of these measures, I find no significant effect of job loss on health change. This adds credibility to the hypothesis that job loss may not cause ill health.

4.3. The effect of job loss on health by subgroups

Columns 1 and 2 of Table VI show how the effect of job loss on health varies with prior expectations about job loss. Column 1 includes a binary indicator for respondents who stated that their risk of involuntary job loss was zero. The table shows the effect of this variable both for laid-off respondents, and for the entire sample. Respondents who did not expect to lose their job faced improving health. The interaction term of zero job loss expectations and business closed is also associated with improving health, but is not statistically significant. Column 2 includes an interaction term of the probability of involuntary job loss and business closed. The coefficient for this interaction term is zero, indicating that the effect of job loss on health does not depend on previous job loss expectations.

Table V. Alternative measures of health

	ADL change (1)	Longevity expectation change (2)	CESD change (3)	First mental health. Diagnosis (4)

Work at 2nd interview				0.217*** (0.028)
Observations	15 218	15 218	15 218	15 218
Pseudo <i>R</i> -squared	0.000	0.001	0.008	0.011

Robust standard errors in brackets, clustered at respondent level. *Significant at 10%; **Significant at 5%; ***Significant at 1%. Estimation includes all variables in Column 4 of Table III; these coefficients are not shown. All columns show ordered probit estimations. Higher values for health change represent worsening health.

Columns 3 and 4 of Table VI examine the role of unemployment in the relationship between job loss and ill health. As shown in Table I, most respondents affected by job loss are not unemployed at the time of the second interview. Many laid-off employees find new employment, although typically at substantially lower wages (see discussion in Section 3). Column 3 includes a binary indicator for respondents who are unemployed at the time of the second interview and an interaction term between unemployment at the time of the second interview and business closed. Unemployment at the time of the second interview is not exogenous to health change if persons with deteriorating health are more likely to become or stay unemployed. The estimation results indicate that unemployment is associated with strongly declining health. However, the interaction terms of business closed and unemployment point to improving health, but is not significantly different from zero. Column 4 includes a binary indicator for respondents who did not work at the time of the second interview and an interaction term between this variable and business closed. As for unemployment, work status at the time of the second interview is not exogenous to health change if respondents with deteriorating health are more likely to stop working. The estimation results show that persons who do not work at the time of the second interview face strongly deteriorating health. However, the interaction term of working at the second interview and business closed is close to zero and not statistically significant. Columns 3 and 4 of Table VI imply that persons with deteriorating health are more likely to become unemployed, and they are more likely to leave the labor force, but for laid-off respondents there is no significant relationship between health change and unemployment or between health change and work status at the time of the second interview.

The estimation results shown in column 1 of Table VII include interaction terms of business closed with gender and marital status, black race, education level, and previous job characteristics. The omitted reference group would be unmarried white females without high school degree. The results suggest that married, black, and more educated respondents might be less affected by the negative health consequences of job loss, while respondents with low wages and with jobs that involve a high degree of stress or physical effort are more affected by job loss. However, these interaction terms are not statistically significant.

Table VII. Effects of job loss interacted with socioeconomic and job characteristics, longer term effects of job loss, and spousal job loss

	Health change	Health change	Health change
Business closed	−0.290 (0.196)		
Married male × business closed	−0.116 (0.153)		
Married female × business closed	−0.155 (0.278)		
Not married male × business closed	0.061 (0.184)		
Black × business closed	−0.151 (0.195)

College × business closed	−0.205 (0.224)		
Job stressful × business closed	0.054 (0.069)		
Job physical effort × business closed	0.066 (0.056)		
Low wage × business closed	0.231 (0.140)		
Business closed in previous Wave		0.098 (0.069)	
Spouse business closed			0.118 (0.077)
Spouse prob. of job loss			−0.001 (0.001)
Observations	14 174	18 233	7 915
Pseudo <i>R</i> -squared	0.01	0.008	0.005

Robust standard errors in brackets, clustered at respondent level. *significant at 10%; **significant at 5%; ***significant at 1%. Estimation in column 1 includes all variables in column 4 of Table III and additional variables for stressful job, job requires physical effort and low wage; columns 2 and 3 include variables for demographics, socioeconomic characteristics, and health behaviors. All columns show ordered probit estimations. Higher values for health change represent worsening health.

Column 2 of Table VII shows the effect of lagged job loss on self-reported health change. It includes a binary indicator, which is set to one, for respondents who lost their job due to business closure in the 2-year period prior to the first interview. This specification examines the effect of job loss on health for a period of 2–4 years after the layoff. The estimation results show no evidence for a longer-lasting effect of business closure on subsequent changes in health. Column 3 of Table VII reports the effects of a spousal job loss on health. The estimation results provide no evidence for an effect of spousal layoffs on the health of respondents.

5. CONCLUSION

In summary, I find no evidence for any significant effects of job loss on health within a period of up to 4 years after job loss. This result is robust across specifications. It holds for various measures of physical and mental health, for the average effect of job loss on health for all laid-off persons, as well as for the effect of job loss on specific groups defined by previous job loss expectations as well as by gender, marital status, race, education, and previous working conditions. There is also no effect of the job loss of a spouse.

These results contradict much of the previous literature that finds strong negative health consequences of unemployment. However, many previous studies do not account for the cause of unemployment, which might be related to ill health. Some previous studies account for this possible

source of endogeneity by examining the effect mass-layoffs on health. They find a negative effect of job displacement on mortality (Eliason and Storrie, 2009, Sullivan and von Wachter, 2009), but not on hospitalization for stress-related diseases (Browning *et al.*, 2006). This study adds support to the findings of Browning *et al.* (2006) that there might be no effect of job displacement on health.

The identification strategy of my study is well suited for identifying the causal effect of job loss on health. This study focuses on people who have lost their job for an exogenous reason – the closure of their previous employer's business. This study also accounts for a detailed list of individual characteristics including the ex-ante subjective probability of involuntary job loss in order to control for differences between individuals who are laid off and individuals who are not laid off.

The results of my study also make it plausible that the inferior health of the unemployed compared to the employed could be explained by reverse causality. Specifically, I find that leaving a job for health reasons is both quite common in this age group, and associated with a rapid deterioration in health (Table V), and that persons with deteriorating health are more likely to become unemployed or leave the labor force (Table VI). This leads me to the cautious conclusion that the absence of any significant effect of job loss on health in this study might indeed unveil that job loss does not cause ill health.

ACKNOWLEDGEMENTS

I thank Padmaja Ayyagari, Han Hong, Ahmed Khwaja, Jan Osterman, Frank Sloan, Alessandro Tarozzi, Curtis Taylor, Nicolas Ziebarth, two anonymous referees, and seminar participants at Duke University, the University of Mannheim, the iHEA conference in Barcelona, and the EU Workshop on econometrics and health economics in Coimbra for valuable suggestions.
